INTRODUCTION

Normal yield tables are presented here for white spruce (*Picea glauca* (Moench) Voss) in interior Alaska. White spruce accounts for 64 percent of the commercial cubic-foot volume and 81 percent of the commercial board-foot volume of this region (Hutchison 1967).¹ These yield tables, like those prepared by Gregory and Haack (1965) for the two principal hardwoods, paper birch (*Betula papyrifera* Marsh.) and quaking aspen (*Populus tremuloides* Michx.), were prepared to show the range of sites in the interior and the effect of site on stand development. They also provide estimates of yield for the range of sites and ages found in the interior.

Although the many limitations of normal yield tables are recognized (Spurr 1952, pp. 260-261), they are of value for interior Alaska where well-stocked, even-aged stands are common and the forests are not being managed. Forests of the interior are, for the most part, inaccessible and little cutting has taken place except for limited local use near population centers. Intensive forest management is still many years off.

¹Names and dates in parentheses refer to Literature Cited on inside back cover.

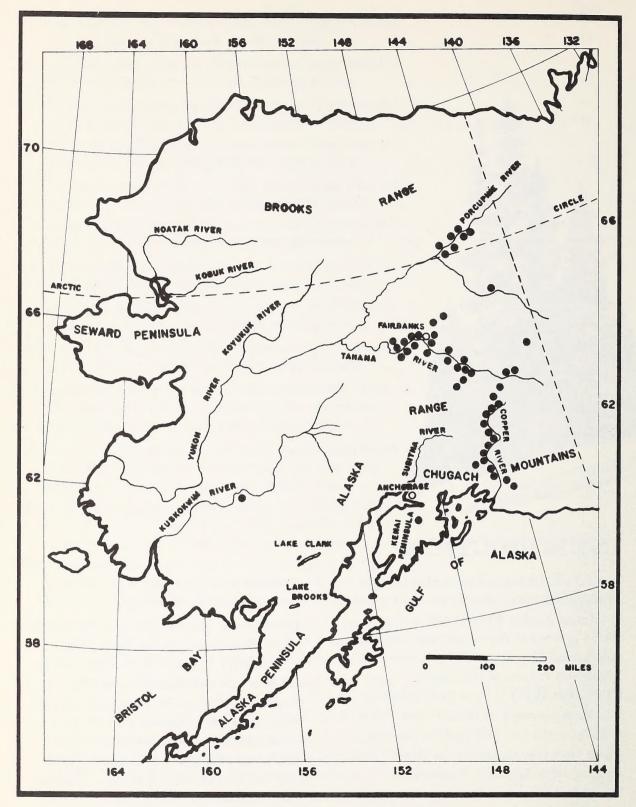

Figure 1. – Location of sample plots. Each black dot represents one or more temporary plots used in this study.

THE FOREST REGION

Alaska's interior comprises some 332,555,000 acres. Sixty-eight percent of this total consists of grassland, brush, swamps, tundra, barren rock, ice, and snow. The remaining 32 percent, or 106,000,000 acres, is forested (Hutchison 1967).

The interior forests are a westward extension of the boreal forests of Canada. Within Alaska, the forests extend westward to about 164^o west longitude on the Seward Peninsula and as far north as the Brooks Range. The Chugach Mountains, bordering the Gulf of Alaska and Bristol Bay to the westward, form the southern boundary. The southern limit of forest types common to the interior is near Lake Brooks on the Alaska Peninsula, about latitude 58^oN. (fig. 1).

GEOGRAPHY

Interior Alaska is characterized by rugged mountains and broad river valleys; the most prominent feature is the Alaska Range, which arcs northeasterly from near Lake Clark on the west to the St. Elias Range on the east. North of the Alaska Range the principal river valleys are those of the Noatak, Kobuk, Yukon, and Kuskokwim Rivers and their tributaries. The Koyukuk, Porcupine, and Tanana Rivers are tributaries of the Yukon River. South of the Alaska Range, the chief river valleys are those of the Susitna and Copper Rivers and their tributaries (fig. 1).

CLIMATE

Alaska's interior has a climate of extreme contrasts. Winter days are short and extremely cold, and summer days are long and mild. Annual precipitation, north of the Alaska Range and on the Copper River plateau to the south, averages 10 to 13 inches — low for a forested region. The summer months receive the heaviest rainfall — close to 2 inches a month (Watson 1959). Tree growth is greatest during June and July when the days are warm and daylight is nearly continuous. Most of this area is also within the zone of discontinuous permafrost, the occurrence of which tends to keep the water table near the soil surface.

South of the Alaska Range, the Susitna Valley and Kenai Peninsula have warmer winters, cooler summers, receive more precipitation (15 to 30 inches annually), and have fewer growing degree days than do areas to the north of the Range (Funsch 1964).

FORESTS

About 21 percent (22-1/2 million acres) of the interior's forested land is classified as commercial; that is, capable of producing at least 20 cubic feet of wood per acre annually. The remaining 79 percent (83 million acres) consists of sparse and stunted woodlands presently considered noncommercial (Hutchison 1967). White spruce, black spruce (*Picea mariana* (Mill.) B.S.P.), tamarack (*Larix laricina* (Du Roi) K. Koch), paper birch, quaking aspen, balsam poplar (*Populus balsamifera* L.), and black cottonwood (*P. trichocarpa* Torr. & Gray) are the native tree species.

White spruce is the most important forest type, covering 57 percent (12.8 million acres) of the commercial forest land. By comparison, paper birch accounts for 23 percent, aspen for 11 percent, and poplar and cottonwood for 9 percent of the commercial forest land (Hutchison 1967). Black spruce is abundant but rarely reaches commercial size. Tamarack occurs as a minor stand component on poorly drained, noncommercial sites north of the Alaska Range.

The interior forests are susceptible to destruction by fire. Low precipitation, high air temperatures, and long hours of sunshine during the summer increase the hazard of fire, especially in the uplands where natural barriers are few.

As a result of past fire history, the uplands typically are covered with dense, even-aged stands of paper birch and quaking aspen. Aspen is limited chiefly to southern exposures whereas birch predominates on northeast- and northwest-facing slopes (Gregory and Haack 1965). The colder north-facing slopes usually support poor stands of black spruce. Although white spruce occurs in pure, even-aged stands in the uplands below about 1,500 feet, most stands are located on moderately well drained soils of lowland sites adjacent to the rivers.

White spruce reaches its best development along the Tanana River and on the south-facing slopes of the Tanana-Yukon uplands. Site quality is generally poorer elsewhere (table 1). Dense spruce stands grow along the major rivers far north of the Arctic Circle, but their site index is low. For example, along the Porcupine River, sample plot trees seldom exceeded 70 feet in height and 12 inches diameter at breast height (d.b.h.); site index averaged 55 (table 1).

CHARACTERISTICS OF WHITE SPRUCE STANDS

White spruce is a hardy tree species that grows throughout Windthrow as an important cause of destruction of interior Alaska on a variety of sites. Although its best development takes place near the base of slopes and on moderately well drained alluvial soils, its range does extend to the northern, western, and altitudinal limits of tree growth.

Above about 1,500 feet and at the limits of tree growth where there is little competition from hardwoods, white spruce develops in pure or nearly pure, sparsely stocked stands. At lower upland elevations, white spruce regenerates following fire both in pure stands and in mixture with the common hardwoods. The reasons for pure spruce stands at these lower upland elevations are not known. Possibly they develop if fire is severe enough to expose mineral soil, if seed is abundant, and if the area receives adequate moisture for germination and survival.

When the uplands regenerate to a spruce-hardwood mixture, the short-lived hardwoods initially outgrow the spruce and maintain an overstory position for 80 or more years until the hardwoods begin to die out. Only then does the spruce assume the dominant stand position.

Stream meanders, sloughs, wet muskegs, and the occurrence of many islands provide effective fire barriers for river-bottom sites. Because of this, ecological succession possibly accounts for most white spruce stands found growing on the wide alluvial flats of the major rivers, where soil erosion and deposition is active. Mature and overmature stands, 100 to 240 years old, occupy extensive areas along most of the major rivers.

river-bottom stands seems unlikely. Periodic flooding over a hundred years deposits a foot or more of alluvium on the forest floor, and root systems become well anchored. Such river-bottom trees are more likely to be snapped off above the ground by strong winds than uprooted.

Pure stands of white spruce are typically well stocked although they often do not appear so. White spruce in Alaska is characteristically narrow crowned, and even the well-stocked stands do not have closed canopies. Crown cover seldom exceeds 50 to 70 percent.

By age 30 years at breast height, basal area of well-stocked stands will reach 126 square feet or more (table 4) in stands of 1,500 or more trees per acre (table 12). At theoretical rotation age (70-150 years, depending on site) 15 to 30 percent of the trees are sawtimber size (larger than 8.5 inches d.b.h.). Most trees are limby.

White spruce stands remain well stocked for 180 years or more. As the mature trees die and openings appear, brush species, principally Sitka alder (Alnus sinuata (Reg.) Rydb.) become established. Remnant spruce may live for 350 years or more. The oldest trees found during this study were along the Tanana River near Fairbanks - they were 329 years old at breast height.

Unless fire again reclaims the site after a stand reaches maturity, a thick insulating layer of organic material accumulates on the soil surface; underlying soils thaw later in the growing season, or may even remain permanently frozen, causing site quality to decrease with time.

GROWTH AND YIELD

TERMS AND MEASURES

Age. – Average breast-height age of the tallest white spruce trees, provided they are not remnants of an earlier stand.

Breast-height age was used because early height development is slow and total age is difficult to determine accurately, particularly in the case of river-bottom stands where alluvial deposits of 1 foot or more may accumulate over the rotation of the stand. Also, decay at ground level in the older stands obscured the annual rings.

Height. — Total height from ground to tip of the tallest tree on a 1/4-acre plot, provided the tree is of average stand age.

Site index. – Height of the tallest tree on a 1/4-acre plot at index age 100 years.

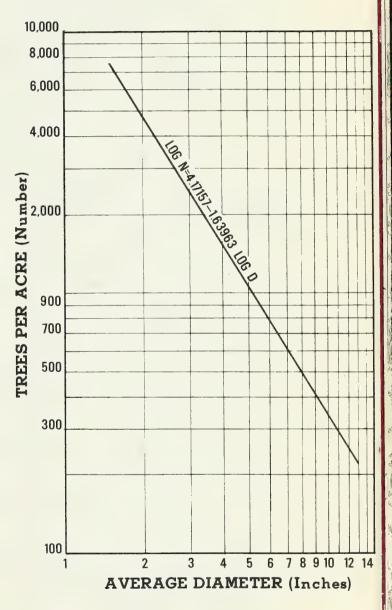

Volume. – Cubic-foot volumes per acre to different merchantability standards, computed with tree volume equations published by Gregory and Haack (1964). Merchantability standards are given in the table headings (tables 17 through 22).

International 1/4-inch board-foot volumes per acre were computed from a tree volume equation (Farr 1967) derived from the same basic data used to develop cubic-foot volume tables (Gregory and Haack 1964). Board-foot volumes per acre are given for trees larger than 8.5 inches, from a 1-foot stump to a 6-inch top inside bark.

Mean annual increment. – Determined by dividing present volume (table 17) by present age. The age of culmination of mean annual increment is the theoretical rotation age. Volume of all trees larger than 4.5 inches d.b.h. is measured in cubic feet from a 1-foot stump to a 4-inch top inside bark.

BASIC DATA

Ninety-nine yield plots were sampled; 97 of these were distributed over the eastern interior, and two were measured along the Kuskokwim River near McGrath (fig. 1). Most of the plots were one-quarter acre in size. Some 1/10- and 1/20-acre plots were used in young stands, and nine 1/3-acre plots were used in older stands on the best sites to insure that at least 100 trees were measured per plot. On 20 of the 1/4-acre plots, the four to six tallest trees were felled and sectioned for height-age determinations to be used in construction of site-index curves. Table 2 summarizes the distribution of yield plots by age and site index. Well-stocked white spruce stands of site index less than 50 or greater than 100 are rare occurrences in the interior. The four plots in the less than 50 site index class in table 2 were sampled from along the Porcupine River north of the Arctic Circle.

The two plots with site quality greater than 100 were sampled from along the Tanana River about 120 miles east of Fairbanks.

An expression of stocking based on the sample data is shown in figure 2.

Data taken on each plot included:

1. Diameter at breast height of all live trees larger than 0.5 inch, by 1-inch classes.

2. Enough total-height measurements (10 to 20) to construct a reliable height-diameter curve.

3. Breast-height age of at least the six tallest white spruce per plot.

4. A description of the plot including latitude, longitude, aspect, slope, and elevation.

ANALYSES

Site index. – The method of Johnson and Worthington (1963) was used to derive the equation:

White spruce site index = height (0.49638+50.36166/age). A Solution of the equation is shown graphically in figure 3 and numerically in table 3. Realignment of the axes, with height as the dependent variable, provides the more traditional solutions (fig. 4, table 4). Q

Because relative height of the four to six tallest trees per plot shifted with time, Dahms' (1963) method of using the tallest tree at any given stand age was used.

Yield estimates. – Equations to estimate basal area per acre, basal area of the average tree, and volumes per acre (tables 5 through 22) were derived by stepwise regression (Dixon 1965). The basic equation used was:

$$\begin{split} Y_{i} &= b_{i0} + b_{i1}A + b_{i2}A^{2} + b_{i3}A^{3} + b_{i4}S + b_{i5}S^{2} + b_{i6}S^{3} \\ &+ b_{i7}SA + b_{i8}S^{2}A + b_{i9}SA^{2} + b_{i10}S^{2}A^{2} + b_{i11}1/A \end{split}$$

where:

- Y₁ = Basal area per acre for trees larger than 0.5 inch d.b.h.
- Y₂ = Basal area per acre for trees larger than 4.5 inches d.b.h.
- Y₃ = Basal area per acre for trees larger than 6.5 inches d.b.h.
- Y₄ = Basal area per acre for trees larger than 8.5 inches d.b.h.
- Y₅ = Average basal area of trees larger than 0.5 inch d.b.h.
- Y₆ = Average basal area of trees larger than 4.5 inches d.b.h.
- Y₇ = Average basal area of trees larger than 6.5 inches d.b.h.

- Y₈ = Average basal area of trees larger than 8.5 inches d.b.h.
- Y₉ = Cubic-foot volume per acre for trees larger than 4.5 inches d.b.h. from a 1-foot stump to a 4-inch top inside bark.
- Y_{10} = Cubic-foot volume per acre for trees larger than 6.5 inches d.b.h. from a 1-foot stump to a 4-inch top inside bark.
- Y₁₁ = Cubic-foot volume per acre for trees larger than 6.5 inches d.b.h. from a 1-foot stump to a 6-inch top inside bark.
- Y₁₂ = Cubic-foot volume per acre for trees larger than 8.5 inches d.b.h. from a 1-foot stump to a 4-inch top inside bark.
- Y₁₃ = Cubic-foot volume per acre for trees larger than 8.5 inches d.b.h. from a 1-foot stump to a 6-inch top inside bark.
- Y₁₄ = International 1/4-inch board-foot volume per acre for trees larger than 8.5 inches d.b.h. from a 1-foot stump to a 6-inch top inside bark.
 - = Breast-height stand age.
- S = Site index.
- b_{ii} = Regression constants.

Quadratic mean diameters² (diameters of trees of mean basal area) corresponding to Y_5 through Y_8 were calculated.

The average number of trees per acre, N_i, was estimated by solving:

 $N_1 = Y_1/Y_5$, $N_2 = Y_2/Y_6$, $N_3 = Y_3/Y_7$, and $N_4 = Y_4/Y_8$

For some combinations of site index and age, the equations for computing partial stand basal area $(Y_2, Y_3, \text{ and } Y_4)$ give higher values than can be expected for the entire stand (Y_1) . Statistically, this is reasonable because the equations were derived independently, by use of stepwise regression. In nature, however, such a condition does not exist. Where the computed Y_2, Y_3 , or Y_4 values were higher than those computed for Y_1 , the Y_1 values were used. The age at which merging of the equations occurs is given for each site class in tables 6, 7, and 8. Merging ages were computed by setting the equations equal to each other and solving. Merging also occurred between cubic-foot equations Y_9 and Y_{10} .

Equations for calculating tabular values and merging points, and the precision of them in terms of the multiple coefficient of determination (R^2) , are given as footnotes to the tables.

Diameter frequencies. – A graphical method of constructing stand tables described by Meyer (1937,

²Curtis, Robert O. Which average diameter? 1967. (In press, J. Forest.)

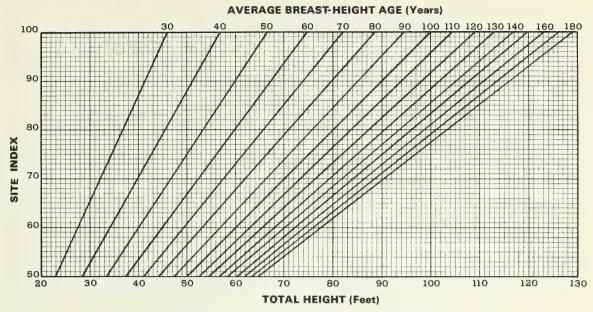

Figure 3. – Site index for white spruce, by breast-height age and height of the tallest white spruce tree per one-fourth acre.

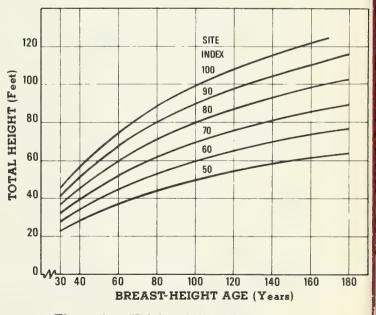

pp. 84-85) was used to develop table 24 which shows, by average stand diameter, the percentage of trees in each 1-inch diameter class. Table 24 may be used with tables 9 and 13 to estimate the number of trees in each diameter class for any site-age combination.

Mean annual increment. — Table 23, which shows mean annual increment per acre for trees larger than 4.5 inches d.b.h., was prepared by dividing the cubic-foot volume by age for each site-age combination in table 17. The age of culmination of mean annual increment is the theoretical rotation age. Sites capable of producing at least 20 cubic feet per acre per year are classified as commercial forest land by Forest Survey; stands producing less are considered noncommercial. An area of site quality 63 would, therefore, be borderline between commercial and noncommercial forest land.

ESTIMATING SITE INDEX

For any white spruce stand that is at least moderately well stocked, site index can be determined by measuring total height of the tallest white spruce tree (per one-quarter acre) of average stand age and estimating breast-height stand age. Stand age must be found by averaging the breast-height age of at least the six tallest white spruce trees per one-quarter acre.

A site index system based on the height of the tallest individual in a stand is easy to apply - an important consideration in comparison with some of the more complicated systems that require 10 to 20 heights of dominants and codominants or dominants alone. Even though the use of more individuals may show a reduction in estimation error, the increase in precision may be small. Dahms (1966) found this to be true of lodgepole pine on the pumice soils of eastern Oregon. The problem encountered in using site index curves based on average height of dominant and codominant trees is that invariably the fieldman will measure heights of just the better dominants.

Area	No. of plots	Minimum and maximum site index	Average site index
Porcupine River	10	41 - 64	55
Tanana River uplands between Fairbanks and Nenana	12	71 – 100	84
Tanana River:			
West of Fairbanks	10	73 – 94	82
East of Fairbanks	20	73 — 106	90
Copper River plateau:			
North of Glennallen	7	54 - 85	70
South of Glennallen	14	50 - 64	58

Table 4. – Height of tallest white spruce, by breast-height age and site index, interior Alaska¹

 $^{-1}$ Tabular values were derived from the equation:

$$H = \frac{5}{0.49638 + 50.36166/A}$$

where: H = height of the tallest white spruce per one-fourth acre

S = site index

A = average breast-height age of at least the six tallest white spruce trees.
